THE FACIAL FEEDBACK HYPOTHESIS AND AUTOMATIC MIMICRY IN PERCEPTION OF SUNG EMOTION

By Lisa Chan

For Ryerson University, Master of Arts, Psychology, 2010

Abstract

Facial mimicry in response to emotional and neutral singing was tested in the context of an emotion judgment task. Participants were tested in two conditions, Perception (n=16) and Imagery (n=21). Participants were presented with video clips showing a singer expressing happy, neutral and sad emotions, and were asked to identify the expressed emotions, as well as rate their intensity. Participants in the Perception group were asked to simply watch the video clips, while participants in the Imagery group were also asked to imagine imitating the song fragment after watching the model singer. Facial electromyography was used to monitor activity in the corrugator supercilii and zygomaticus major muscles. Results showed more corrugator muscle activity for sad than happy trials, and more zygomaticus activity for happy than sad trials. No differences were found between conditions, suggesting that mimicry is an automatic process, not requiring encouragement prompted by imagery.

Acknowledgments

I would like to thank first and foremost, my supervisor, Dr. Frank Russo, for his guidance, expertise, and support. I am also grateful for my wonderful thesis committee, Dr. Tara Burke, Dr. Stephen Want, and Dr. Margaret Moulson, for their advice and insight. To my family and friends, thank you for your support and encouragement. Finally, to my fellow SMART Lab Members, thank you for your assistance, and for being a great group of individuals to work with!
